ABSTRACT

An unusual case of multiple round filling defects in colon in a patient with family history of rectal malignancy and its pathogenesis has been described. Family history may not be present in 25%. Usually there is family history of polyp or colorectal carcinoma at 40 years or younger. The young patient may suffer from unexplained rectal bleeding, diarrhea, abdominal pain. Some may be asymptomatic until they develop carcinoma.

Keywords: Colonic polyp; Desmoid; Rectal malignancy.

INTRODUCTION

Familial Adenomatous Polyposis (FAP) is autosomal dominant inherited disorder. Usually there are more than 100 polyps. All can develop carcinoma of the colon if not treated. The genetic defect gives rise to phenotypic spectrum of diseases such as FAP, Gardner's syndrome, Turcot's syndrome, attenuated Adenomatous Polyposis Coli (AAPC) etc.¹ An unusual case of rectal mass in a patient with family history of FAP is discussed.

Case report

A female of 37 years presented with per rectal bleeding for 8 years to the Department of Radiology of Tribhuvan University Teaching Hospital in 2007 for a barium enema study. Her elder brother had similar symptoms and he had undergone colectomy. Her late father also suffered from recurrent episodes of per rectal bleeding. Two big brothers died in childhood. Her sister had also died of distension of abdomen. She has two children who are asymptomatic.

Her double contrast barium enema study shows multiple round filling defects involving the whole colon including the rectum (Fig. 1).

Fig.1: Double contrast barium enema study of the patient.

Barium study of her brother showed irregular large filling defect in the rectum due to malignant mass in addition to multiple small filling defects (Fig. 2).

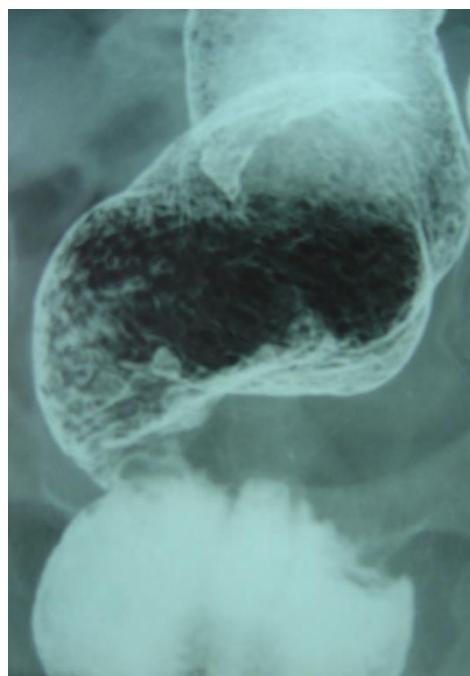

Fig. 2: Barium study of the patient's brother showed irregular large filling defect in the rectum due to malignant mass in addition to multiple small filling defects.

DISCUSSION

Adenomatous Polyposis Coli (APC) gene is located in the long arm of chromosome 5. APC protein promotes apoptosis of B-catenin. B-catenin inactivate APC gene. Every colonic epithelial cell has one mutated and one normal copy of APC. Inactivation of normal copy occurs by deletion or mutation. Increase in B-catenin completely removes tumour suppressive function.

The frequency of this disease is 1:7000-31000. All races are vulnerable. Sex incidence is 1:1. Age of onset is 16 years (36 years in AAPC). The patients are often asymptomatic. They may develop fibromas, palpable abdominal \ rectal mass may be present. Associated findings are adenomas of duodenum (100%), hamartomatous polyps in stomach (50%), desmoids (12%), perianampullary Carcinoma (5%).²

Imaging studies used are flexible sigmoidoscopy, colonoscopy, gastro endoscopy, and Barium studies, CT scan for desmoid, skull and dental x-rays. Screening methods are ophthalmic examination, flexible sigmoidoscopy (1-2 years from 12-35 years; 3 years thereafter); genetic testing- DNA markers with linkage analysis. Complications are colorectal carcinoma, duodenal \ perianampullary adenocarcinoma, medullblastoma, hepatoblastoma, thyroid & adrenal carcinoma, rectal carcinoma. Peri-ampullary tumours develop in 11% by the age of 50 years and 52% by the age of 75.³

desmoids, adenocarcinoma of duodenum or papilla after colectomy. In patients who develop colorectal carcinoma, 100% mortality is observed. The onset of carcinoma is 39 years (54 years in AAPC). Family history may not be present in 25%. Usually there is family history of polyp or colorectal carcinoma at 40 years or younger. The young patient may suffer from unexplained rectal bleeding, diarrhea, abdominal pain. Some may be asymptomatic until they develop carcinoma.¹

On examination, congenital hypertrophy of retinal pigment epithelium, osteomas of skull and mandible, odontomas and dentigerous cyst, epidermoid cyst, Median life expectancy is 42 years in untreated and this can be extended greatly if colectomy is performed. Family members should be informed about screening. Carcinoma surveillance is essential after colectomy.³

Duodenal and perianampullary cancer is the most common cause of cancer death in patients with familial adenomatous polyposis who have undergone colectomy. Endoscopic surveillance of upper gastrointestinal adenomas is recommended for patients with familial adenomatous polyposis.⁴ The prevalence of duodenal adenomatosis among FAP patients varies from 50% to greater than 90%, while only few patients (3-5%) develop duodenal cancer. Perianampullary adenomas seem to carry a high risk of malignant transformation. The sensitivity of endoscopic procedures for early detection of severely dysplastic or malignant duodenal lesions is low, and the prognosis of duodenal cancer is poor. Thus the

question arises whether it is possible to define a subgroup of high-risk patients for duodenal malignancy, and whether severe duodenal adenomatosis should lead to an aggressive prophylactic surgical approach.⁵

The Spigelman classification stratifies cancer risk in Familial Adenomatous Polyposis (FAP) patients with duodenal adenomatosis. High-Resolution Endoscopy (HRE) and Narrow-Band Imaging (NBI) may identify lesions at high risk.⁶ The Fujinon Intelligent Color Enhancement (FICE) significantly increases adenoma detection rate in FAP patients but does not change any Spigelman stage and thus does not modify patient's prognosis and treatment strategies.⁷

HRE has raised the quality of endoscopic imaging considerably. Consequently, re-evaluation of the original Spigelman classification system seems advisable. Chromoendoscopy further increases detection of duodenal adenomas in FAP but without considerable change in Spigelman stage. Ampullary adenomas are commonly found in FAP and are best visualized using a side-viewing endoscope. Therefore, a combination of forward-viewing HRE and chromoendoscopy with side-viewing endoscopy for the periampullary region seems useful for surveillance of duodenal adenomatosis in FAP.⁸

After staining a larger number of duodenal polyps were found than at the standard endoscopic examination, the difference being statistically significant. Chromoendoscopy may improve diagnostic yield of endoscopy.⁹

Jejunal adenomas in FAP patients are reported occasionally and can progress

into adenocarcinoma with a poor prognosis. In the future a subset of FAP patients benefitting from jejunal surveillance should be identified.¹⁰ Clinically significant jejunal polyposis in FAP is rare, even in high-risk patients with advanced duodenal disease.¹¹
